Short communication

Distinct recruitment of basolateral amygdala-medial prefrontal cortex pathways across Pavlovian appetitive conditioning

Abstract

Associative learning can enable environmental cues to signal food and stimulate feeding, independent of physiological hunger. Two forebrain regions necessary in cue driven feeding, the basolateral area of the amygdala and the medial prefrontal cortex, communicate via extensive, topographically organized connections. The basolateral nucleus (BLA) sends extensive projections to the prelimbic cortex (PL), and our aim here was to determine if this pathway was selectively recruited during cue-food associative learning. The anterior and posterior basolateral nuclei are recruited during different phases of cue-food learning, and thus we examined whether distinct pathways that originate in these nuclei and project to the PL are differently recruited during early and late stages of learning. To accomplish this we used neuroanatomical tract tracing combined with the detection of Fos induction. To identify projecting neurons within the BLA, prior to training, rats received a retrograde tracer, Fluoro-Gold (FG) into the PL. Rats were given either one or ten sessions of tone-food presentations (Paired group) or tone-only presentations (Control group). The Paired group learned the tone-food association quickly and robustly and had greater Fos induction within the anterior and posterior BLA during early and late learning compared to the Control group. Notably, the Paired group had more double-labeled neurons (FG + Fos) during late training compared to the Control group, specifically in the anterior BLA. This demonstrates selective recruitment of the anterior BLA-PL pathway by late cue-food learning. These findings indicate plasticity and specificity in the BLA-PL pathways across cue-food associative learning.

1. Introduction

Cues that signal food can increase the motivation to procure and consume food in the absence of hunger across species (e.g., Birch, McPhee, Sullivan, & Johnson, 1989; Weingarten, 1983; for reviews see Holland & Petrovich, 2005; Petrovich, 2013; Petrovich & Gallagher, 2003). Environmental cues can gain this ability through associative learning, such as during Pavlovian appetitive conditioning. In this preparation, a neutral cue from the environment (conditioned stimulus, CS) is repeatedly followed by food (unconditioned stimulus, US), which innately evokes feeding behaviors (unconditioned response, UR). The CS then becomes the predictor of the US and ultimately drives the same behaviors (conditioned response, CR). These acquired abilities are well established behaviorally; however, much less is known about the neural plasticity, particularly at a circuit level, that underlies cue-food learning.

The amygdala, specifically the basolateral area, is important for appetitive associative learning and subsequent behaviors (Cole, Powell, & Petrovich, 2013; Corbit & Balleine, 2005; for reviews see Crombag, Bossert, Koya, & Shaham, 2008; Everitt, Cardinal, Parkinson, & Robbins, 2003; Gallagher & Schoenbaum, 1999; Holland & Petrovich, 2005; Wassum & Izquierdo, 2015), and its function is conceptualized to involve ‘tagging’ biologically relevant incoming stimuli and then informing other brain systems via complex and distributed connectional networks (e.g., Swanson & Petrovich, 1998; Weiskrantz, 1956). The amygdala is a heterogeneous structure (Swanson & Petrovich, 1998), and recent work found that distinct nuclei within the basolateral area (containing the lateral, basolateral [BLA] and basomedial nuclei) were differentially recruited during early and late cue-food learning (Cole et al., 2013). Specifically, the anterior basolateral nucleus (BLAa, Swanson, 2004; also known as the magnocellular division based on its morphology, Pitkänen, Savander, & LeDoux, 2003; Savander, Go, LeDoux, & Pitkänen, 1995) was the only amygdalar nucleus that displayed a significant increase in activation (measured with Fos induction) during early learning, which was maintained throughout training. The posterior basolateral nucleus (BLAp, Swanson, 2004; also known as the parvocellular division based on its morphology, Pitkänen et al., 1997; Savander et al., 1995) was recruited during late training along with other amygdalar nuclei that are connected with the BLAa. These results
demonstrate specificity in the recruitment of amygdalar nuclei, and the differential recruitment across early and later learning suggests plasticity within the BLAa and, potentially, with its connectional targets.

The BLA has extensive connections with the medial prefrontal cortex (Hoover & Vertes, 2007; Kita & Kitai, 1990; Reppucci & Petrovich, 2016), which is important for the executive function and control of feeding and other motivated behaviors (Dalley, Cardinal, & Robbins, 2004; O’Doherty, 2011; Swanson & Petrovich, 1998). Specifically, the ventromedial prefrontal cortex, including the prelimbic (PL) and infralimbic (ILA) areas, is critical in appetitive cue learning (Ashwell & Ito, 2014; Baldwin, Holahan, Sadeghian, & Kelley, 2000; Baldwin, Sadeghian, & Kelley, 2002; Burgos-Robles, Bravo-Rivera, & Quirk, 2013; Cole, Hobin, & Petrovich, 2015; Corbit & Balleine, 2003). This area is necessary for feeding driven by learned food cues (Cole, Mayer, & Petrovich, 2015; Petrovich, Ross, Holland, & Gallagher, 2007), can be stimulated to drive food intake (Blasio, Steardo, Sabino, & Cottone, 2014; Land et al., 2014; Mena, Sadeghian, & Baldo, 2011) and alters activity in downstream neural regions mediating feeding behaviors (Mena, Selleck, & Baldo, 2013). Furthermore, disruption of the BLA-mPFC pathway attenuates reward-seeking driven by learned contextual and discrete cues (Fuchs, Eaddy, Su, & Bell, 2007; Mashhoon, Wells, & Kantak, 2010; Stefanik & Kalivas, 2013). Nevertheless, the functional connectivity of the BLA-PL pathways has not been investigated during the acquisition of cue-food associations.

Within the medial prefrontal cortex, the BLA most densely innervates the PL, with topographically distinct pathways originating in the BLAa and BLAp (Hoover & Vertes, 2007; Kita & Kitai, 1990; Reppucci & Petrovich, 2016). The BLAa and BLAp are recruited during different phases of cue-food learning (Cole et al., 2013), suggesting that the BLAa-PL and BLAp-PL pathways may also be differentially engaged. The goal of the current study was to determine whether the BLA neurons that send direct projections to the PL are selectively activated during cue-food learning and whether distinct pathways that originate in the BLAa and BLAp are differentially recruited during early and late learning of cue-food associations.

2. Methods

In order to identify BLA-to-PL projecting neurons, rats were iontophoretically injected with the retrograde tracer Fluoro-Gold (FG) into the PL. After recovery, rats received either one training session (early learning; S1) or ten training sessions (late learning; S10) of Pavlovian appetitive conditioning. Each training session included eight presentations of a tone CS that for the Paired condition co-terminated with the delivery of two food pellets (US). Rats in the Control group received the CS presentations in the behavioral chambers followed by the US delivery in their home cage at a random interval after each session. The primary measure of learning was the percentage of time rats expressed food cup behavior during the CS. Rats were perfused 90 min after the cessation of S1 or S10 for brain tissue collection. The Control groups did not receive the US on perfusion day. The brain tissue was processed for S10 for brain tissue collection. The Control groups did not receive the US on perfusion day. The brain tissue was processed for

3. Results

3.1. Behavior

During early training (Session 1), the Paired group displayed increasingly more food cup behavior during CSs throughout the session compared to the Control group, signifying learning (Fig. 1A). Repeated measures ANOVA (Training group × CS) found a significant effect of CS ($F_{(1,18)} = 2.713, P < 0.05$), but no effect of training group ($F_{(1,18)} = 2.793, P > 0.05$), or interaction ($F_{(1,18)} = 1.239, P > 0.05$). To assess learning during the session, further analysis compared behavior between the first half and the second half of the session (four CSs each). The Paired group displayed more food cup behavior during the last four CSs compared to their responding during the first four CSs ($P < 0.05$) and compared to the Control group ($P < 0.05$; Fig. 1B). There were no differences between the groups during the first four CSs ($P > 0.05$) or during pre-CS intervals ($P > 0.05$).

Over ten sessions of training, the Paired group showed an increase in food cup behavior during the CSs, while the Control group displayed minimal and non-specific food cup behavior throughout training. Repeated measures ANOVA (Training group × Session) revealed a significant effect of training group ($F_{(1,14)} = 139.018, P < 0.0001$), a significant effect of session ($F_{(1,14)} = 6.968, P < 0.001$) and a significant interaction across sessions ($F_{(1,14)} = 9.781, P < 0.001$). During session 2, the Paired group had higher food cup responding compared to the Control group ($P < 0.05$; Fig. 1C), but similar responding during the pre-CS and CS intervals ($P > 0.05$). Throughout sessions 3–10, the Paired group showed high responding specifically to the CS compared to their pre-CS responding ($P < 0.05$) and compared to the behavior of the Control group during the CS ($P < 0.05$). During the last session of training (session 10), repeated measures ANOVA (Training group × Time period [CS or pre-CS]) found a significant effect of training group ($F_{(1,14)} = 8.287, P < 0.05$), a significant effect of CS vs Pre-CS time period ($F_{(1,14)} = 63.816, P < 0.0001$), and a significant interaction ($F_{(1,14)} = 64.858, P < 0.0001$). The Paired group showed higher food cup behavior during the CS than the Control group ($P < 0.001$) with no difference in pre-CS behavior between the groups ($P > 0.05$; Fig. 1D).

3.2. Neural analysis

The location and spread of FG injection sites were analyzed throughout the rostro-caudal extent of the prelimbic cortex (PL) based on the Swanson brain atlas (Swanson, 2004). Acceptable injections (see Supplemental Materials) were confined predominantly within the PL (n = 36) and were centered within the mid-rostro-caudal extent of the PL (Fig. 2: Levels 6, 7 and 8; +4.2, +3.6, and +3.2 mm from bregma, respectively). The final group numbers were S1 Paired (n = 10), S1 Control (n = 10), S10 Paired (n = 8), and S10 Control (n = 8). Importantly, the total numbers of retrogradely-labeled neurons were similar across groups (Fig. 3B), confirmed by two-way ANOVAs (Training group × Session) in the BLAa (Training group: $F_{(1,12)} = 2.477, P > 0.05$; Session: $F_{(1,12)} = 0.585, P > 0.05$ and BLAp (Training group: $F_{(1,12)} = 0.542, P > 0.05$; Session: $F_{(1,12)} = 0.119, P > 0.05$), signifying that any differences found in the number of double-labeled (FG + Fos) neurons are not due to variances in the number of FG-labeled neurons. Representative images of FG and Fos labeled neurons in the BLAa are shown in Fig. 3A. Fors injection in the BLA neurons was examined during early (session 1; S1) and late (session 10; S10) tone-food conditioning. Within the BLAa, the Paired group had more Fos-positive neurons than the Control group during S1 and S10 (Fig. 3B). The two-way ANOVA (Training group × Session) revealed a significant effect of training group ($F_{(1,12)} = 16.722, P < 0.01$), but no effect of session ($F_{(1,12)} = 0.609, P > 0.05$), or interaction ($F_{(1,12)} < 0.000, P > 0.05$). Post hoc analysis confirmed the Paired group had significantly more Fos-positive neurons than the Control group during S1 ($P < 0.01$) and S10 ($P < 0.05$), replicating previous findings using this protocol (Cole et al., 2013).
There was a similar pattern within the BLAp of higher Fos induction in the Paired group compared to Control group, but there was also an overall decrease in Fos induction across training (Fig. 3B). Within the BLAp, a two-way ANOVA (Training group × Session) of Fos induction found a significant effect of training group ($F_{(1,32)} = 11.279, P < 0.01$) and a significant effect of session ($F_{(1,32)} = 6.369, P < 0.05$), but no interaction ($F_{(1,32)} = 0.378, P > 0.05$). The Paired group had more Fos-positive neurons than the Control group during S1 ($P < 0.001$) and a trend towards significance during S10 ($P = 0.087$). Overall, there were more Fos-positive neurons in the S1 groups compared to the S10 groups ($P < 0.05$).

To examine the activation of the BLA-PL pathways, the total number of double-labeled neurons (FG + Fos) within the BLAa and BLAp was quantified (see Supplemental Materials for specifications) and compared across groups and sessions. We found selective Fos induction in the PL projecting BLAa neurons, but not BLAp neurons, in the Paired group during S10. In the BLAa, two-way ANOVA (Training group × Session) of Fos induction in BLAa neurons that project to the PL revealed a significant effect of training group ($F_{(1,32)} = 7.818, P < 0.01$), but no effect for session ($F_{(1,32)} = 0.123, P > 0.05$), or interaction ($F_{(1,32)} = 0.290, P > 0.05$). Post hoc analysis confirmed the Paired S10 group had more double-labeled neurons than the Control S10 group ($P < 0.001$) and a trend towards significance during S10 ($P = 0.087$). Overall, there were more Fos-positive neurons in the S1 groups compared to the S10 groups ($P < 0.05$).

4. Discussion

In the current study, we examined the functional activation of the BLA-PL pathways during the acquisition of Pavlovian appetitive conditioning. We found significantly more Fos induction in BLAa-to-PL projecting neurons in the Paired group compared to the Control group. This effect was statistically reliable specifically during the late training, but not during the early training. This finding demonstrates recruitment of the BLAa-PL pathway across training, suggesting plasticity during cue-food associative learning. Interestingly, Fos induction in projecting neurons within the BLAp was similar between training groups throughout tone-food conditioning, demonstrating activation of the BLAp-PL pathway was similar in the Paired and Control groups throughout learning. Together, these results show that only the BLAa-PL pathway, but not the BLAp-PL pathway, is activated during well-learned cue-food associations. Additionally, we analyzed total Fos induction in the BLAa and BLAp and found higher overall induction in the Paired groups compared to the Control groups during both phases of learning. This difference between overall activation and the activation of specific BLA-to-PL projecting neurons highlights the importance of identifying how specific neurons are recruited within a critical neural cortical underlying behavior.

Here, the retrograde tracer injections were aimed at the PL, an area substantially innervated by the BLAa. Our focus was on the BLAa, because that was the only amygdalar cell group recruited during early cue-food training, suggesting it is informing its neural connections during appetitive conditioning (Cole et al., 2013). Nevertheless, the BLAa and BLAp have distinct connections...
with the medial prefrontal cortex, and while the BLAa has dense connections with the PL and the anterior cingulate area, the BLAp is connected more heavily with the ILA compared to the PL (Hoover & Vertes, 2007; Kita & Kitai, 1990; Little & Carter, 2013; Reppucci & Petrovich, 2016; Sesack, Deutch, Roth, & Bunney, 1989; Swanson & Petrovich, 1998). In accordance, our injections in the PL resulted in labeling and analysis only within the rostral half of the BLAp, and thus the current study did not capture the more substantial projections from the BLAp to the ILA. Given the ILA was also recruited during late learning of cue-food associations, similar to the PL (Cole, Hobin, et al., 2015), it is possible the BLAp-ILA pathway may be important during appetitive associative learning. Furthermore, the current study found more overall Fos induction in the BLAp (total Fos induction in both projecting and non-projecting neurons) during early and late training in the Paired group, whereas Cole et al. (2013) found recruitment of the BLAp only during late learning. A methodological difference in sampling is a potential reason why these results differ. Cole et al. (2013) examined the entire extent of the BLAp (the entire dorso-ventral and rostro-caudal area within the nucleus), while in the current study the total Fos was counted within the area of substantial PL projection (only the rostral portion of the BLAp).

In addition to the functional differences found in the current study and aforementioned distinct connections with the mPFC, the BLAa and BLAp also differ in their connections with other forebrain areas. Within the amygdala, the BLAp sends substantial direct pathways to the central amygdala, while the BLAa reaches it indirectly through its connections to the BLAp (Savander et al., 1995; Swanson & Petrovich, 1998). Based on its forebrain connections, the BLAa was characterized as a part of the frontotemporal system, and it projects to the nucleus accumbens and caudoputamen, as well as to the medial frontal and adjacent somatomotor cortical areas (Kita & Kitai, 1990; Swanson & Petrovich, 1998). Importantly, it does not send direct projections to hippocampal formation, the hypothalamus, or the bed nuclei of the stria terminals (Dong, Petrovich, & Swanson, 2001; Petrovich, Canteras, & Swanson, 2001; Swanson & Petrovich, 1998). The BLAp was characterized as a part of the main olfactory system, and it projects to the nucleus accumbens and the substantia innominata, as well as the hippocampal formation, the hypothalamus, and bed nucleus of
the stria terminalis, (Petrovich et al., 2001; Reppucci & Petrovich, 2016; Swanson & Petrovich, 1998).

The findings from the current study and previous work support the notion that the BLAa is a critical early ‘processor’ during appetitive associative learning. Here, we found recruitment of the BLAa during early learning in agreement with Cole et al. (2013). The BLAa was the only forebrain region to show selective activation during early learning, while the amygdalar and forebrain targets of its inputs were recruited during late training (Cole et al., 2013; Cole, Hobin, et al., 2015). Furthermore, electrophysiological recordings also provide evidence that the BLA precedes and influences other cortical processing. Single-unit recordings found that the BLA is activated prior to the activation of the gustatory cortex during palatability processing (Grossman, Fontanini, Wieskopf, & Katz, 2008), and BLA inactivation can alter gustatory cortex responses (Piette, Baez-Santiago, Reid, Katz, & Moran, 2012). This early processing function of the BLA may capture its role in tasks with reward predictive cues, including cue-potentiated eating (Holland, Petrovich, & Gallagher, 2002), discriminative stimulus responding (Ishikawa, Ambroggi, Nicola, & Fields, 2008), second-order conditioning (Hatfield, Han, Conley, Gallagher, & Holland, 1996), devaluation (Hatfield et al., 1996), and Pavlovian to instrumental transfer (Blundell, Hall, & Killicross, 2001; for review see Wassum & Izquierdo, 2015). The current study suggests that the BLA processing is relayed to the PL during acquisition, potentially enabling this pathway to later control cue driven reward behaviors. Indeed, inhibition of the BLA-PL pathway decreased conditioned reward seeking (Fuchs et al., 2007; Mashhoon et al., 2010; Stefanik & Kalivas, 2013), and BLA inactivation caused a disinhibition of the PL activity during reward seeking, resulting in a deficit in conditioned place preference for morphine (Sun & Laviollette, 2012).

The BLAa is a cortical part of the amygdala (Swanson & Petrovich, 1998), and its output from pyramidal neurons can influence the PL through monosynaptic (McDonald, 1992; Sotres-Bayon, Sierra-Mercado, Pardilla-Delgado, & Quirk, 2012) and polysynaptic pathways involving inhibitory interneurons (Dilgen, Tejeda, & O’Donnell, 2013; Floresco & Tse, 2007; Gabbott, Warner, & Busby, 2006; Perez-Jaranay & Vives, 1991; Sun & Laviollette, 2012). Inactivation of the BLA decreased PL pyramidal neuron activity, suggesting a monosynaptic pathway (Sotres-Bayon et al., 2012). Alternatively, BLA stimulation increased activity within interneurons, which inhibited PL pyramidal neurons, suggesting a polysynaptic pathway (Dilgen, Tejeda, & O’Donnell, 2013). Through these pathways the BLA input can critically control PL activity, either through excitation or inhibition, and ultimately control behavioral outcomes.

5. Conclusions

In conclusion, we found plasticity and selectivity within the BLAa-PL pathways across Pavlovian appetitive conditioning. The BLAa-PL, and not the BLAp-PL, pathway was selectively recruited during cue-food learning and, importantly, this recruitment suggests plasticity in BLAa-PL communication across training. These results suggest the BLA is important during initial appetitive learning, and its communication with the medial prefrontal cortex increases throughout learning as a cue becomes predictive of food to control behavior.
